

I apologize for the inactivity that has befallen Image of the Month.

I hope to resume it now, monthly, and shall try to make up for the tardiness with an unusual image.

I had never heard or seen this entity and then saw three cases of it within 6 months! The first two I photographed only but did not treat. The third was my and Justin Cheesman's patient.

These three people all have the same condition, which can be diagnosed bedside. Note all three have extremities that are fixed in the position in which you see them. These arms can not be moved by active or passive range of motion.

The first, an older woman, and the third, a younger man, were pedestrian vs car with outstretched hands at the moment of impact. What do they have and how do you fix it and what special considerations accrue to such a dx? (Hint: "boo boo shoulder" gets no credit.)
